16 **Abstract**

17 The Yucatán Peninsula (YP) has a complex hydroclimate with many proposed drivers of
18 interannual and longer-term variability, ranging from coupled ocean-atmosphere processes to
19 frequency of tropical cyclones. The mid-Holocene, a time of higher Northern Hemisphere
20 summer insolation, provides an opportunity to test the relationship between Yucatán Peninsula
21 precipitation and ocean temperature. Here we present a new, ~annually resolved speleothem
22 record of stable isotope (δ^{18}O and δ^{13}C) and trace element (Mg/Ca and Sr/Ca) ratios for a section
23 of the mid-Holocene (5.2-5.7 kyr BP), before extensive agriculture began in the region. A meter-
24 long stalagmite from Río Secreto, a cave system in Playa del Carmen, Mexico, was dated using
25 U-Th geochronology and layer counting, yielding multi-decadal age uncertainty (median 2SD of
26 ± 70 years). New proxy data were compared to an existing late Holocene stalagmite record from
27 the same cave system, allowing us to examine changes in hydrology over time, and to
28 paleoclimate records from the southern YP. The δ^{18}O, δ^{13}C and Mg/Ca data consistently indicate
29 higher mean precipitation and lower precipitation variability during the mid-Holocene compared
30 to the late Holocene. Despite this reduced variability, multi-decadal precipitation variations were
31 persistent in regional hydroclimate during the mid-Holocene. We therefore conclude that higher
32 summer insolation led to increased mean precipitation and decreased precipitation variability in
33 the northern YP, but that the region is susceptible to dry periods across climate mean states.
34 Given projected decreases in wet season precipitation in the YP's near future, we suggest that
35 climate mitigation strategies emphasize drought preparation.
36
37 Keywords: Yucatán Peninsula, speleothems, hydroclimate, trace elements, oxygen isotopes,
38 carbon isotopes, drought.
39

40 Key points:
41   - Stable isotope data confirm a wetter, less variable mid-Holocene climate in the northern
42   Yucatán Peninsula compared to the late Holocene
43   - Speleothem Mg/Ca has potential for use as a precipitation proxy in the Yucatán Peninsula

1 Introduction

The Yucatán Peninsula (YP) harbors diverse ecosystems, including the Mesoamerican barrier reef and tropical rainforests, and has been inhabited by Maya societies for thousands of years. Biological systems and human societies in the region developed under limited surface and groundwater availability and have therefore been vulnerable to hydroclimate extremes. Under future climate warming scenarios, the YP is projected to receive less wet season precipitation compared to current precipitation (Karmalkar et al., 2011). The important role of hydroclimate variability in shaping the past, present and future of human societies and ecosystems motivates efforts to better document past hydroclimate changes in the YP and their relationships to regional conditions and external forcings.

There has been extensive research on the potential drivers of YP climate variability during the Common Era (CE; past 2000 years), and on the role of drought in the decline of Maya civilization during the Preclassic (droughts at ~180 and 240 CE) and Terminal Classic Periods (750-950 CE) (*e.g.* Curtis et al., 1996; Hodell et al., 1995; Medina-Elizalde et al., 2010, 2016a). Climate simulations and paleoclimate records suggest that late Holocene precipitation in the YP was linked to North Atlantic climate variability. Potential controls on precipitation amount include changes in sea surface temperature (SST), sea level pressure (SLP) (Bhattacharya et al., 2017), tropical cyclone variability (Frappier et al., 2007, 2014; Medina-Elizalde et al., 2016a), and the mean position of the Intertropical Convergence Zone (ITCZ) (*e.g.* Bush et al., 2009; Lechleitner et al., 2017; Ridley et al., 2015; Pollock et al., 2016). These climate variations are likely linked, further complicating diagnostics (McGee et al., 2014). YP precipitation variability also suggests a link with El Niño-Southern Oscillation (ENSO) in the Pacific (Frappier et al., 2014; Giannini et al., 2000, Lachniet et al., 2017; Medina-Elizalde et al., 2016a, 2016b, 2017; Metcalfe et al., 2009; Pollock et al., 2016; Stahle et al., 2012).

The mid-Holocene is of particular interest to investigate the role of external forcing on hydroclimate variability in the Caribbean region. During the mid-Holocene, solar radiation was higher in the Northern Hemisphere (NH) during the boreal summer relative to the late Holocene and present (Hoddell et al., 1995; Laskar et al., 2004) and ENSO variability was markedly decreased (Carré et al., 2014; Chen et al., 2016; Emile-Geay et al., 2016). Limited data on Atlantic and Caribbean sea surface temperatures are available for this time period, but paleotemperature reconstructions indicate that global temperatures reached a local maximum around 6500 years before present (Kaufman et al., 2020). Based on increased NH summer radiation during the mid-Holocene, it is possible that there was stronger seasonality and higher summer SSTs in the North Atlantic and Caribbean (Marcott et al., 2013; Marsicek et al., 2018). Given modern connections between the North Atlantic and Caribbean hydroclimate (*e.g.* Bhattacharya et al., 2017) and previous paleo research in the southern YP (*e.g.* Pollock et al., 2016; Wahl et al., 2014; Winter et al., 2020), we expect that the mid-Holocene northern YP was wetter and less variable in precipitation than the late Holocene or the present.

Data from speleothems and sediment cores in the southern YP are broadly consistent with the expectation of wetter mid-Holocene conditions (*e.g.* Pollock et al., 2016; Wahl et al., 2014; Winter et al., 2020). However, existing paleoclimate records do not address the northeast YP, which is drier than the southern YP at present, nor do they offer a consensus regarding the

90 magnitude and frequency of precipitation variability during the Holocene. Published
91 paleoclimate records in the YP are based on proxy data from various archives, including
92 speleothems (*e.g.* Akers et al., 2016; Frappier et al., 2014; Pollock et al., 2016, Winter et al.,
93 2020) and lake, sinkhole, wetland, and swamp sediment cores (Anderson & Wahl, 2016; Curtis
94 et al., 1996; Douglas et al., 2015; Guttierez-Ayala et al., 2012; Hodell et al., 2005; Metcalfe et
95 al., 2009; Rosenmeier et al., 2002; Roy et al., 2017). Therefore, there is a rich body of work that
96 serves as a foundation for further studies.
97
98 Although there are several valuable paleoclimate records available in the YP region (recent
99 examples include Kennett et al., 2012; Medina-Elizalde et al., 2010, Pollock et al., 2016; Richey
100 et al., 2015, Ridley et al., 2015, Wahl et al., 2014; Winter et al., 2020), many existing archives do
101 not have high enough temporal resolution (and low enough age uncertainty) to investigate
102 interannual to decadal hydroclimate variability in the region. Furthermore, the majority of the
103 existing records come from Belize and Guatemala (*e.g.* Pollock et al., 2016; Wahl et al. 2014;
104 Winter et al., 2020), so there is a paucity of data about the northern YP, including parts of
105 present-day Mexican states of Quintana Roo, Campeche, and Yucatán. Winter et al. (2020)
106 highlight the importance of considering the late versus mid-Holocene with sufficient complexity
107 — despite existing data, more granular records (spatially and temporally) are beneficial.
108 Therefore, there is a need for climate archives with high temporal resolution from the northern
109 YP to investigate changes in climate variability in the mid-Holocene.
110
111 In order to refine our understanding of hydroclimate variability in the YP and its underlying
112 drivers during the mid-Holocene, we present stalagmite δ^{18}O, δ^{13}C, Mg/Ca, and Sr/Ca records
113 spanning the interval between 5.2 and 5.7 kyr before present (BP). The stalagmite we use, named
114 RS1, was collected in April 2013 from an isolated chamber in the Río Secreto Cave system (RS),
115 located in the northeastern YP (Figure 1A). An extensive drip water monitoring system was
116 installed in 2014; RS1 was sampled closest to Drip Station A referenced in Lases-Hernandez et
117 al. (2019). RS1 is a ~1 m tall calcite stalagmite, which was partially collapsed at the time of
118 collection. It presents visually distinct lamination, allowing development of an age model based
119 on laminae counting and U-series dating (see Methods). Stalagmite δ^{18}O and δ^{13}C have often
120 been used to infer changes in precipitation in this region (*e.g.* Medina-Elizalde et al., 2010;
121 Ridley et al., 2015; Pollock et al., 2016), while Mg/Ca and Sr/Ca have not been examined
122 previously in the YP, but have been interpreted to reflect precipitation amount in other settings.
123
124 This study examines the new stalagmite record in comparison to another stalagmite-based
125 precipitation record, known as Itzamna, from the same well-studied cave, spanning ~3 to 1.6 kyr
126 BP (Medina-Elizalde et al., 2016a). Stalagmite proxy records from the same location allow us to
127 contrast inferred mid- and late Holocene hydroclimate variability despite the limited growth
128 interval of each individual sample, and decrease the uncertainty associated with comparing
129 stalagmite proxy records from different locations and cave environments. Furthermore, this
130 research focuses on a site located north of existing records, in present-day Quintana Roo (Figure
131 1A).
132
133 *1.1 Regional climate*
134 The whole YP experiences a strong seasonality in precipitation amount (Figure 1B), with over
135 90% of rainfall occurring between April and December in the southern YP (Anderson &Wahl,

136   2016). The rainy season occurs in the summer and is often interrupted by decreased rainfall in
137   July or August (Anderson & Wahl, 2016; Karmalkar et al., 2011; Lases-Hernandez et al., 2019;
138   Muñoz et al., 2008). About 70% of annual rainfall occurs between June and November (Medina-
139   Elizalde et al., 2016b). Maximum precipitation often occurs in September, when the ITCZ is at
140   its northernmost position and Atlantic tropical cyclone frequency peaks (Kovacs et al., 2017;
141   Lases-Hernandez et al., 2019) (Figure 1B). Strong easterly winds, known as the Caribbean Low
142   Level Jet (CLLJ), bring moisture from the warm Caribbean Sea to the YP (Karmalkar et al.,
143   2011; Muñoz et al., 2008); if enhanced, the CLLJ drives increased moisture transport and
144   convergence in the region (Karmalkar et al., 2011; Mestas-Nuñez et al., 2007; Muñoz et al.,
145   2008). The large-scale structure of the vertically-integrated water vapor fluxes associated with
146   the CLLJ links the Caribbean and Gulf of Mexico regions to climate regimes in the US,
147   particularly during boreal summer (Mestas-Nuñez et al., 2007; Muñoz et al., 2008). We note that
148   historical precipitation variability in the YP region is linked to that of the broader Caribbean
149   region, particularly the northern sector, as indicated by spatial-temporal correlation analyses of
150   instrumental precipitation records (*e.g.* Medina-Elizalde et al., 2017). In addition, it is important
151   to note that up to 20% of cumulative western North Atlantic annual precipitation comes from
152   tropical cyclones (Larson et al., 2005); this indicates that tropical cyclones play an important role
153   in YP precipitation amount.
154
155   Within the YP, there are differences in precipitation amount; this is part of the motivation for
156   new paleo records from a less-studied area of the YP. Monthly climatology from 1901 to 2002
157   reveals that Playa del Carmen, where RS1 was collected, receives significantly less total wet
158   season rainfall than other recently studied sites in the southern YP (Pollock et al., 2016; Wahl et
159   al., 2014; Winter et al., 2020) (Figure 1A). However, RS is also more influenced by tropical
160   storms than are the other sites; a study comparing all the Mexican states noted that Quintana Roo
161   had the highest number of tropical cyclone landfalls on the east coast of Mexico from 1970 to
162   2010 (Farfán et al., 2014). Our analysis of historical (1842 – 2020 CE) storm tracks at each site
163   indicated that there were 67 tropical cyclones near RS, 33 each at Chen Ha (Pollock et al., 2016)
164   and Lago Puerto Arturo (Wahl et al., 2014), and 9 at Grutas del Rey Marcos (Winter et al., 2020)
165   within 60 nautical miles of each site (Knapp et al., 2010, 2018; Landsea & Franklin, 2013);
166   tropical cyclones included tropical storms through Category 5 hurricanes, but not extratropical
167   storms or tropical depressions. Climate models based on future emissions scenarios indicate that
168   tropical cyclone landfalls may increase in the YP (Appendini et al., 2019), though another study
169   predicted lower wet seaon precipitation in the YP (Karmalkar et al., 2011). Due to the current
170   frequency of tropical storms in the northeastern YP, it is important to have more climate data
171   from this highly vulnerable region.
172
173   *1.2 Climate proxies*
174   Stalagmite $\delta^{18}O$ records in Mesoamerica, including the YP, are interpreted to reflect changes in
175   precipitation amount (*e.g.* Akers et al., 2016; Lachniet et al., 2017; Medina-Elizalde et al., 2016a,
176   2016b), with more negative $\delta^{18}O$ values indicating increased precipitation, as expected from an
177   amount effect, or the empirical relationship between precipitation amount and $\delta^{18}O$ composition
178   observed in the tropics from seasonal to interannual timescales (Burns et al., 1998; Dansgaard,
179   1964; Lases-Hernandez et al., 2019; Vuille et al., 2003). Changes in $\delta^{13}C$ in stalagmites reflect a
180   number of local processes associated with the soil cover, epikarst and vadose zone (Genty et al.,
181   2006). Some of the most common controls include the ratio of C3 to C4 vegetation above the

182 cave (Burns et al., 2016; Dorale et al., 1998; Webb et al., 2004;) and the amount of degassing in
183 the vadose zone (Lachniet et al., 2004). Rainfall amount can influence drip water $\delta^{13}C$ (and
184 therefore stalagmite $\delta^{13}C$) by affecting soil moisture and organic matter production, bedrock
185 dissolution, degassing, and prior calcite precipitation (PCP) (Genty et al., 2006; Ridley et al.,
186 2015; Wong and Breecker, 2015).
187
188 In low-latitude caves where the overlying vegetation is expected to remain relatively stable over
189 time, stalagmite $\delta^{13}C$ variability can reflect precipitation amount in the Central American region,
190 as observed in Belize (Ridley et al., 2015). Low precipitation enhances degassing and PCP,
191 increases bedrock carbon contributions and decreases soil bio-productivity, all ultimately
192 increasing drip water $\delta^{13}C$ and stalagmite $\delta^{13}C$ (*e.g.* Ridley et al., 2015; Pollock et al., 2016). In
193 the YP, we assume that the type of vegetation remained relatively constant over the ~500 years
194 captured in this research, or that the effects of vegetation changes were substantially smaller than
195 those of precipitation changes; this is a reasonable assumption because we focus on the mid-
196 Holocene, before extensive deforestation and maize agriculture (Anderson & Wahl, 2016;
197 Aragón-Moreno et al., 2012; Islebe et al., 2018). Furthermore, sediment core studies from
198 Guatemala indicate that there was persistent closed canopy forest during the mid-Holocene,
199 despite the relatively high occurrence of natural or human-generated fires (Anderson & Wahl,
200 2016.) Therefore, we will use stalagmite $\delta^{13}C$ as a proxy for moisture availability in RS1.
201
202 Although stalagmite $\delta^{18}O$ and $\delta^{13}C$ records have been widely interpreted as hydroclimate
203 proxies, they are not without complexities. Stalagmite $\delta^{18}O$ can be influenced by changes in
204 moisture source and upstream water vapor history. Similarly, stalagmite $\delta^{13}C$ can be impacted by
205 soil and karst processes not directly related to precipitation variability (Genty et al., 2001;
206 Hellstrom et al., 1998). Moreover, both $\delta^{18}O$ and $\delta^{13}C$ can also be affected by kinetic
207 fractionation, especially in low humidity environments. Despite these potentially complicating
208 issues, previous studies in the YP and Belize present multiple lines of evidence that stalagmite
209 $\delta^{18}O$ and $\delta^{13}C$ can record local and regional precipitation amount (Medina-Elizalde et al., 2010,
210 2016a, 2016b, 2017; Pollock et al., 2016; Ridley et al., 2015). We analyze Mg/Ca and Sr/Ca
211 ratios to examine their magnitude and frequency variability and to test interpretations from the
212 more conventional $\delta^{18}O$ and $\delta^{13}C$ records. This is the first study that examines Mg/Ca and Sr/Ca
213 ratios in a stalagmite from the YP region.
214
215 Many stalagmite analyses in other locations have applied Mg/Ca and Sr/Ca for hydroclimate
216 reconstruction (*e.g.* Cruz et al. 2017; Fairchild et al., 2001; Lewis et al., 2011; Roberts et al.,
217 1998; Steponaitis et al., 2015). Trace element to calcium ratios can track PCP and/or water-rock
218 interactions, which change based upon soil and water conditions in the local environment (*e.g.*
219 Cruz et al., 2017; Fairchild et al., 2000, 2001; Sinclair et al., 2012). In drier conditions, water
220 moves more slowly through the karst above a cave, so it has more time to degas and become
221 saturated with calcite (Tremaine and Froelich, 2013). During PCP, Mg and Sr are preferentially
222 excluded from the calcite crystal lattice, so Mg/Ca and Sr/Ca ratios in groundwater increase
223 (Fairchild et al., 2000). Non-PCP interactions between water and host rock, also called calcite
224 recrystallization, can also occur in the karst, especially when water residence time is high during
225 dry periods. The chemical signature of recrystallization is similar to that of PCP, but with a
226 different relationship between Mg/Ca and Sr/Ca (Sinclair et al., 2012). Therefore, Mg/Ca and
227 Sr/Ca in stalagmites provide an estimate of aquifer recharge and water availability that can serve

228   as an independent hydroclimate proxy, providing a method to examine whether stalagmite $\delta^{18}O$
229   primarily reflects changes in local moisture availability (Tremaine & Froelich, 2013).

233   *(this work), Lago Puerto Arturo (Wahl et al., 2014), Chen Ha (Pollock et al., 2016), and Grutas*
234   *del Rey Marcos (Winter et al., 2020). b. Monthly precipitation in the 0.5° x 0.5° grid cell closest*
235   *to Río Secreto. All rainfall data are from the Centro de Ciencias de la Atmósfera at the*
236   *Universidad Nacional Autónoma de México (UNAM) v0705 dataset, 1950 to 2002 (Mendez and*
237   *Caetano, 2007).*
238
239   **2 Methods**
240
241   *2.1 Regional setting and cave system*
242   We collected the stalagmite outside the city of Playa del Carmen, Quintana Roo, in the northeast
243   YP (20°35.244'N, 87°8.042'W, 10-20m above sea level) (Figure 1A). The Río Secreto Cave (RS)
244   entrance is about 5 km from the Caribbean coast. Temperature and relative humidity in RS have
245   been monitored ~continuously since 2014. Annual mean temperature in the collection chamber
246   varied by 0.1°C, from 24.6 to 24.7°C (Medina-Elizalde et al., 2016b; Lases-Hernandez et al.,
247   2019). The steady temperature limits the effect of calcification temperature on stalagmite $\delta^{18}O$
248   ($\delta^{18}O_{calcite}$). RS has a relative humidity of 99.6 ± 0.9% throughout the year (Medina-Elizalde et
249   al., 2016b; Lases-Hernandez et al., 2019).
250
251   Three years of drip water $\delta^{18}O$ ($\delta^{18}O_{drip}$) monitoring at 16 drip sites indicated that $\delta^{18}O_{drip}$
252   reflects the $\delta^{18}O$ composition of precipitation ($\delta^{18}O_{precip}$), and that evaporation does not influence
253    $\delta^{18}O_{drip}$ (Lases-Hernandez et al., 2019). The average $\delta^{18}O_{drip}$ is -3.9 ± 1‰ (± 2SD; n = 1043 drip
254   samples collected over 3 years throughout the RS cave system; each sample represents drip water
255   collected for ~48 hours), and the amount-weighted $\delta^{18}O_{precip}$ is -3.7‰ (n = 36 monthly rainfall
256   samples) (Lases-Hernandez et al., 2019). Therefore, the cave drip water accurately records
257   regional $\delta^{18}O_{precip}$ within typical variability. Although the permeable vadose zone is thin (~10
258   m), rainfall infiltration rates vary within the cave, with some drip sites showing increased
259   discharge immediately after rainfall events and others lagging by up to three months (Lases-
260   Hernandez et al., 2019).

261
262 Modern dripwater analyses also showed that Mg/Ca and Sr/Ca decreased significantly during the
263 transition from a dry hydrological year (only 53% of historical mean annual precipitation) to the
264 wettest period studied with >1500 mm in one year (Lases-Hernandez, 2020). Furthermore,
265 farmed calcite analyses indicate that there is active PCP occurring in RS (Lases-Hernandez,
266 2020). In farmed calcite grown over approximately 2 years, there are positive correlations
267 between Mg/Ca and stable isotope data, but no significant correlation between Sr/Ca and stable
268 isotope ratios (Lases-Hernandez, 2020); however, Lases-Hernandez (2020) argues that the lack
269 of correlation with Sr/Ca could be due to the limited variations in precipitation amounts captured
270 in farmed calcite; there was no farmed calcite experiment during the driest hydrological year in
271 2016.
272
273 Drip water samples closest to the RS1 collection site (Drip Station A) show muted ~2‰ intra-
274 annual (seasonal) variability in $\delta^{18}O$ (Lases-Hernandez et al., 2019), and annual mean $\delta^{18}O_{drip}$
275 similar to the amount-weighted annual mean $\delta^{18}O_{precip}$, which suggests that this chamber has a
276 large reservoir with a mixture of seasonal and seepage flow that averages approximately one year
277 of rainfall accumulation (Lases-Hernandez et al., 2019); most recently, the water residence time
278 was estimated to be 4 to 15 months (Lases-Hernandez et al., 2020). Therefore, this study focuses
279 on variability at annual or greater scales. The stalagmite was sampled for proxies with the aim of
280 producing ~annual resolution data. Therefore, we do not expect to resolve individual tropical
281 cyclone events in the record.
282
283 *2.2 U-Th dating, age modeling and microstratigraphy*
284 The age model for RS1 is constrained by U-Th dating of 16 horizons distributed throughout the
285 length of the stalagmite, performed at MIT and including replicates (Tables 1 and 2, Figure 2).
286 Dating samples weighing ~150 mg were drilled with a vertical mill. Powders were dissolved and
287 spiked with a $^{229}Th–^{233}U–^{236}U$ tracer. Based on methods detailed in Edwards et al. (1987), U and
288 Th were isolated using co-precipitation with Fe oxyhydroxides, and eluted using columns with
289 AG1-X8 resin. A total procedural blank was included with each set of dating samples. U and Th
290 fractions were measured on a Nu Plasma II-ES MC-ICP-MS, as described in Burns et al. (2016).
291 We used an initial $^{230}Th/^{232}Th$ ratio of $4.4 \pm 2.2 \times 10^{-6}$ to correct for initial ^{230}Th (Taylor &
292 McLennan, 1985). Other initial ratios were also tested, but were not used because they did not
293 change the stratigraphic order of the dates. All ages are reported as years before present (yr BP),
294 where present is 1950 (Table 2).
295
296 Close to the bottom of the stalagmite (794 mm from the top), we observed a ~50 mm-long darker
297 region that looked more similar to the outer crust than to the rest of the stalagmite (Figure 3c).
298 There were no visible layers within the darker region, suggesting that the layering was dissolved
299 and recrystallized with newer crust. XRD analysis showed that this region is calcite with added
300 silica (supporting information). RS1 was found partially collapsed, so we infer that this dark area
301 is a diagenetically altered segment. The top of the dark region was used as the cutoff for all
302 analyses, so the dark portion and layers below were not included in this study. Visual inspection
303 also revealed a potential hiatus near the top of the sample (Figure 3d), visible as a color change
304 in the calcite and a 2 mm-thick brown layer. Therefore, the region above the deposited dark
305 material (the top 23 mm) was also excluded from climate analysis or age-depth calculations.
306

307   Six of the 16 total dates were not included in the final age model due to low reproducibility,
308   location outside hiatuses, or proximity to possible dissolution features (Table 2; supporting
309   information). Replicates from the same depth were discarded if they did not overlap within 2SD,
310   and samples within 10 mm of a possible dissolution feature were not included.
311
312   Age-depth relationships were calculated with the COPRA program (Breitenbach et al., 2012) in
313   MATLAB (version R2018b). The age-depth model was based on the median of 2000 Monte
314   Carlo simulations of 8 unique U-Th dates (10 including replicates). We calculated upper and
315   lower bounds of the 95% confidence interval (CI) to accurately report the uncertainty of the age-
316   depth model. The median age model and the 95% CI limits all fall within the 2SD uncertainty of
317   each U-Th date. The oldest part of the stalagmite used in this study was dated to 5809 ± 79 yr BP
318   and the youngest was 5234 ± 134 yr BP. Therefore, based on U-Th results, the useable portion of
319   the stalagmite spans 575 ± 107 years.
320
321   RS1 shows a high deposition rate with visually distinct ~2 mm-thick layers throughout the
322   stalagmite, likely reflecting annual deposition (Figure 3). The layers were distinct enough to
323   count and measure in photographs or hand sample, allowing for counting without microscopy or
324   thin sections. We performed visual counts of the same vertical extent, which yielded 463 ± 38
325   layers (mean ± 2SD of multiple counts by GSM and GC). The U-Th age and layer count
326   overlapped within uncertainty, so we established a layer count-enabled age-depth model.
327
328   We used two U-Th dates (one from the top and one from the bottom) as markers of absolute age:
329   working from the top anchor date, we counted layers upwards to reach the top of the stalagmite
330   (stopping at the hiatus), then went back to the anchor and counted layers downward between
331   other U-Th data points to measure relative change in age. We repeated this process with the
332   lower anchor, counting downward to the bottom (stopping at the dark excluded area), then
333   upward between each U-Th date. There was a two year discrepancy between the counted age
334   from the top versus bottom anchors, so we averaged them to make the counted model. We used
335   the date second from the bottom as an anchor (instead of the date closest to the bottom) because
336   of a major shift in growth rate based on U-Th age-depth modeling that was not replicated in the
337   stalagmite layer counting. With this method, we generated a simplified age-depth model based
338   on a cubic function ($r^2 > 0.99$; Figure 2) which was used to calculate ages for the time series of
339   geochemical proxies. All age uncertainties reported in this study are based on the 95% CI of the
340   U-Th age model. For a demonstration of how the oxygen isotope record varies when plotted on
341   the layer count-enabled age model versus the median age-depth model from U-Th ages only, see
342   supporting information.

Individual layers (orange) are deposited from bottom to top, with visible changes in thickness over time and changes in growth axis (straight lines). b. Same as a, without annotations. c. Darker region without visible layers (surrounding the white rectangle); the top of the darker region was used as the cutoff for analyses, so the region and the white segment below it were not used in this paper. d. Potential hiatus near the top of RS1. e. Full stalagmite. Colored boxes indicate location of images shown in a-d.

2.3 Proxy measurements ($\delta^{18}O$ and $\delta^{13}C$; Mg/Ca and Sr/Ca)

369 Calcite samples for stable isotope analysis were drilled at a ~2 mm resolution in a continuous
370 track parallel to the growth axis (n = 335 samples). The $\delta^{18}O$ and $\delta^{13}C$ analyses were carried out
371 using a Thermo Scientific MAT253 Stable Isotope Ratio Mass Spectrometer online coupled to a
372 Kiel IV at University of California Santa Barbara. About 40-50 µg of each sample were reacted
373 using 105% phosphoric acid addition. The evolving CO_2 was cryogenically cleaned before
374 introduction into the mass spectrometer. The $\delta^{18}O$ and $\delta^{13}C$ data are reported on the Pee Dee
375 Belemnite (PDB) scale. The precision of the $\delta^{18}O$ and $\delta^{13}C$ analysis, assessed by analyzing NBS
376 19 standards, was ±0.07‰ and ±0.05‰ (2SE), respectively.

378 Additional samples (weight = ~2 mg) were drilled for trace element analysis at a ~2 mm
379 resolution in locations within 0.25 mm of the stable isotope powder samples (Section 2.3); for
380 any difference larger than 0.25mm, the two types of data are reported at separate depths. Each
381 sample was dissolved and diluted with 3% nitric acid. Standards with similar Mg/Ca and Sr/Ca
382 ratios and concentrations were prepared using single-element standards. Analyses of Mg, Sr, and
383 Ca were performed at MIT on an Agilent 7900 ICP-MS in no-gas mode. Data were corrected for
384 blank intensities, isotopic abundances, and instrumental drift. Relative deviation in standards
385 during one day of analysis averaged 4% (n = 5 standards per day) after these corrections.
386 Replicate runs of identical solutions on different days also varied by an average of 4%. Replicate
387 powders drilled from the same depth but at different distances from the growth axis varied by 1%
388 or less in both Mg/Ca and Sr/Ca. All future references to trace elemental ratios in this work will
389 be referring to Mg/Ca and Sr/Ca.

391 *2.4 Data analysis*
392 We used Spearman's rank correlation, a non-parametric correlation analysis, to test for
393 relationships between the proxies. We used a two-tailed correlation and p-values < 0.05 were
394 considered significant. The rationale behind using Spearman's rank correlation instead of a
395 parametric correlation analysis, like Pearson's correlation coefficient, was to remove the
396 assumption of a linear relationship between the proxies. Instead, Spearman's ρ measures
397 monotonic relationships. A monotonic relationship is more likely than a linear relationship
398 between geochemical proxies controlled by different physical mechanisms, even if they are all
399 controlled (at a high level) by hydroclimate; in other words, we expect both $\delta^{18}O$ and Mg/Ca to
400 increase with drying, but we do not expect Mg/Ca to increase linearly with $\delta^{18}O$. We also used a
401 wavelet toolbox (Grinsted et al., 2004) with MATLAB versions 2018b and 2020a for wavelet
402 analyses of periodicity (supporting information).

404 **Results**
405 *3.1 U-Th dating and age model development*
406 This stalagmite has precise age control, with age model uncertainty substantially lower than
407 those found in nearby stalagmites of similar age due to its low detrital Th content (*e.g.* Akers et
408 al., 2016; Pollock et al., 2016; Winter et al., 2020; Table 1); the median 2SD age uncertainty of
409 U-Th dates was ±70 years. Therefore, RS1 and Itzamna are the oldest stalagmite records from
410 the YP with median age uncertainty <100 years (Medina-Elizalde et al., 2017).

412 After establishing the layer count-enabled age-depth model, we found that the useable portion of
413 the stalagmite grew from 5727 ± 79 to 5264 ± 134 yr BP, or 463 years (2SD uncertainty based
414 on U-Th dates).

415
416 *3.2 Stable isotopes*
417 *3.2.1 Comparison to modern drip water*
418 We sampled RS1 continuously at 2 mm resolution (n = 335 samples) in a region of the
419 speleothem modeled to span 463 years, meaning that each sample averaged ~1.3 years; all proxy
420 data were resampled to annual resolution to remove potential effects of sampling frequency and
421 variable growth rate. Mean $\delta^{18}O_{calcite}$ was -5.50 ± 1.02‰ and mean $\delta^{13}C_{calcite}$ was -9.43 ± 1.99‰
422 (n = 463 points; mean ± 2SD; see supporting information for statistics without resampling).
423 Mean $\delta^{18}O_{drip}$ in the modern RS cave system is -3.9 ± 1‰ (VSMOW; ± 2SD). Using the
424 Tremaine et al. (2011) equation for equilibrium fractionation and temperature = 24.5˚C, we
425 calculate that equilibrium precipitation of calcite would yield $\delta^{18}O_{calcite}$ = -4.8‰. This value
426 overlaps with $\delta^{18}O_{calcite}$ in the late Holocene stalagmite from RS (Itzamna $\delta^{18}O_{calcite}$ = -4.8 ±
427 0.1‰; mean ± 2SE) within error, suggesting late Holocene precipitation at or near equilibrium.
428
429 For a back of the envelope calculation of potential drip water composition in the mid-Holocene,
430 we assume mean cave air temperature was still 24.5˚C. The reversed Tremaine et al. (2011)
431 equilibrium calculation, using $\delta^{18}O_{calcite}$ = -5.5‰, suggests $\delta^{18}O_{drip}$ would have been
432 approximately -4.6‰. This more negative value (in comparison to modern drip water, -3.9‰)
433 supports previous research showing that the mid-Holocene was wetter than the late Holocene, as
434 detailed in the Discussion.
435
436 *3.2.2 Timeseries analysis*
437 $\delta^{18}O_{calcite}$ and $\delta^{13}C_{calcite}$ are significantly positively correlated with each other in the RS1growth
438 period (Figures 4 and 5; ρ = 0.507, p << 0.001); furthermore, when the record was broken into
439 50-year-long windows, they are significantly correlated in 8 out of 9 windows. Although some
440 research has linked covariation in $\delta^{18}O$ and $\delta^{13}C$ to kinetic fractionation (*e.g.* Lachniet et al.,
441 2004), previous work in this cave found that kinetic fractionation was not significant and that
442 relative humidity is near 100% throughout the year (Lases-Hernandez et al., 2019; Medina-
443 Elizalde et al., 2016a); therefore, we suggest that the correlation between $\delta^{18}O_{calcite}$ and $\delta^{13}C_{calcite}$
444 is due to their common dependence on hydrologic variability.
445
446 There were four short periods with $\delta^{18}O$ ratios 2SD less than the mean, interpreted as wet periods
447 that ended at 5551 ± 50, 5493 ± 40, 5351 ± 54, and 5299 ± 65 yr BP (Figure 4). There were also
448 five similarly short periods with $\delta^{18}O$ at least 2SD greater than the mean, interpreted as dry
449 periods, ending at 5668 ± 43, 5571 ± 65, 5404 ± 44, 5363 ± 50, and 5308 ± 63 yr BP (Figure 4).
450 Note that absolute age is based on the layer count-enabled age model and the 2SD age
451 uncertainty is based on the U-Th age model. During each of these events, both wetter and drier,
452 $\delta^{18}O$ values >2SD outside the mean (interpreted as the culmination of the event) lasted for less
453 than 10 years, but were part of a longer period of change (decades-long).

Figure 4. $\delta^{18}O$, $\delta^{13}C$, Mg/Ca and Sr/Ca data for the growth period of RS1, a stalagmite from the YP, resampled to annual resolution. Vertical bars highlight periods with $\delta^{18}O$ values at least 2SD greater than (tan) or less than (blue) the mean. See supporting information for a version of this figure without resampling.
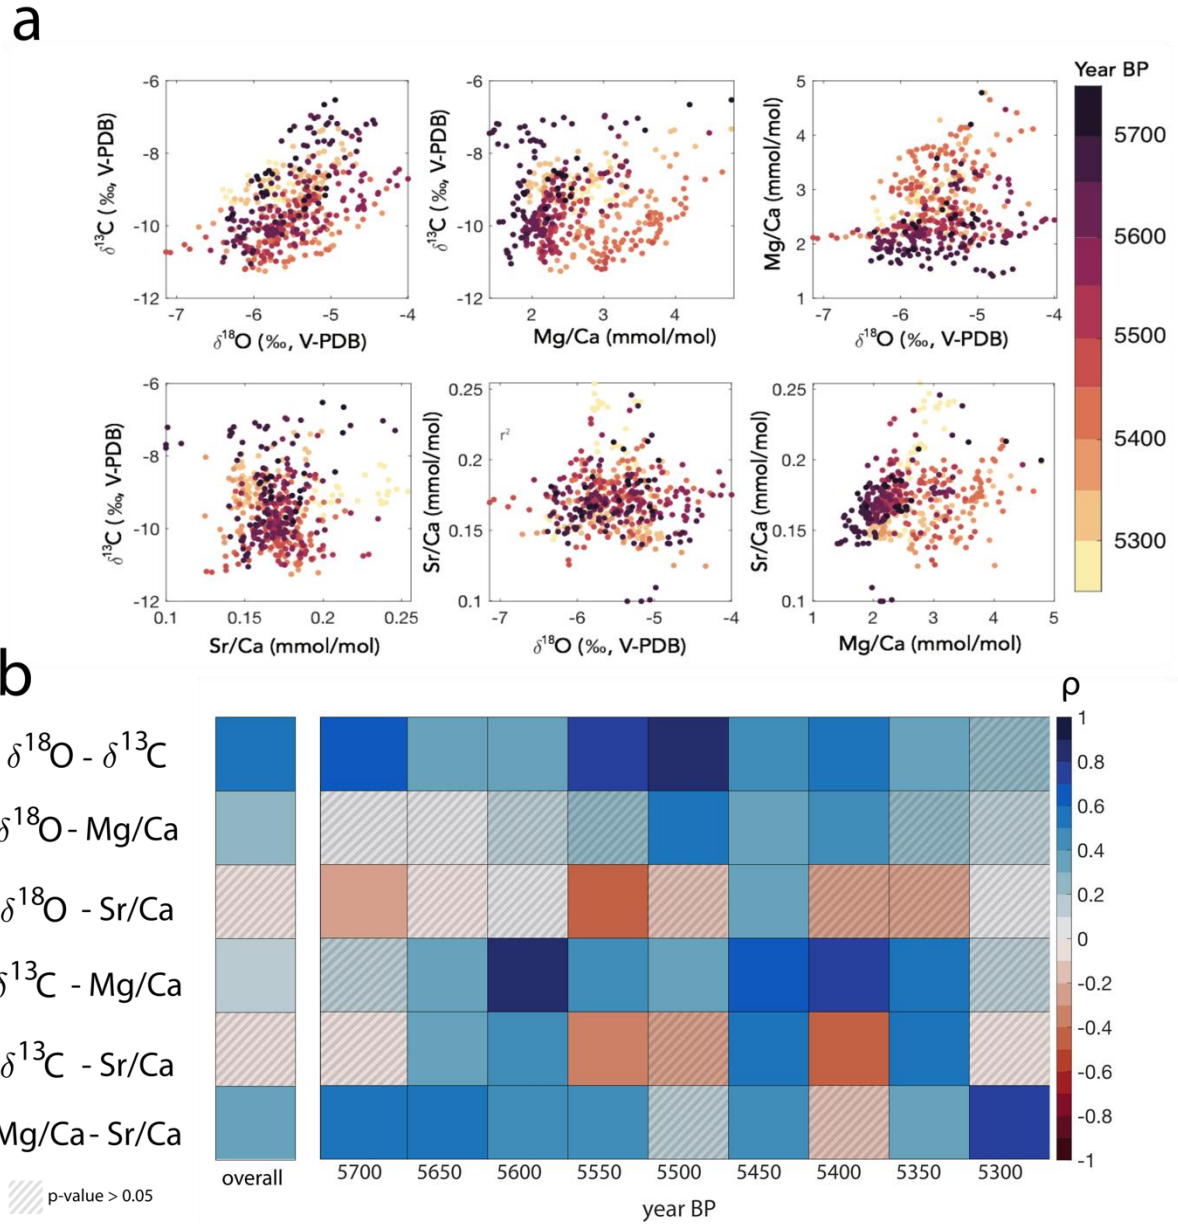

Figure 5. A. Cross plots of trace element to calcium ratios and stable isotope data measured in RS1. All data have been resampled to annual resolution to remove sampling bias and are colored according to their age. B. Correlation coefficient (ρ) for Spearman's rank correlation tests on 50-year-long windows and overall. Cross hatching shows p-value > 0.05, which is not significant.

3.3 Trace elements

Our results show that mean mid-Holocene Mg/Ca was 2.61 ± 1.29 mmol/mol and Sr/Ca was 0.17 ± 0.05 mmol/mol ($\pm 2SD$). Spearman's rank correlations showed a weak but significant correlation between annual Mg/Ca and Sr/Ca data ($\rho = 0.35$, p-value $\ll 0.01$; Figure 5), meaning

472   that Mg and Sr share some common controls. The youngest 50 years (5300 to 5250 yr BP) have
473   the highest correlation ($\rho = 0.76$, p-value $\ll 0.01$), perhaps because Mg/Ca and Sr/Ca both
474   increase during that period (at the same time as a short increase in $\delta^{18}O$), interpreted as drying. It
475   is possible that this period was the beginning of a severe dry event that produced the hiatus that
476   ended the RS1 record.

477

478   We tested whether the lack of correlation was due to sub-decadal noise by applying a low-pass
479   Butterworth filter at 2-year and 5-year frequencies. The correlation only increased a small
480   amount ($\rho = 0.36$ for 2-year low-pass and $\rho = 0.37$ for 5-year low-pass); the lack of significant
481   increase in rank correlation indicates that sub-decadal noise was not the primary difference
482   between Mg/Ca and Sr/Ca. Given these results, we hypothesize that Sr/Ca did respond to
483   hydroclimate changes, but Sr incorporation was additionally influenced by growth rate and axis
484   changes.

485

486   There is low but significant correlation between Mg/Ca and $\delta^{18}O_{calcite}$ ($\rho = 0.25$, p-value $\ll 0.01$)
487   and $\delta^{13}C$ ($\rho = 0.10$, p-value $= 0.027$) throughout the record (Figure 5). Correlations between
488   Sr/Ca and stable isotope data were not significant, yielding $|\rho| < 0.06$ and p-values > 0.3 for both
489    $\delta^{18}O$ and $\delta^{13}C$ (Figure 5).

490

491   We also tested correlations within 50-year-long windows, rather than in the full record, to allow
492   for changes in the initial trace element composition of dripwater through time. Within these
493   windows, Sr/Ca and Mg/Ca are more correlated with $\delta^{13}C$ than they are with $\delta^{18}O$: trace element
494   ratios and $\delta^{13}C$ are significantly positively correlated in more windows (Sr/Ca = 4/9, Mg/Ca =
495   7/9) than trace elements and $\delta^{18}O$ (Sr/Ca = 1/9, Mg/Ca = 3/9) (Figure 5).

496

497   That said, there are also several instances where Mg/Ca and Sr/Ca both increase dramatically,
498   sometimes as much as two-fold. Many of the increases in trace element ratio values coincide
499   with elevated stable isotope values (indicating drier conditions), despite a weaker Sr/Ca response
500   (Figures 4 and 5). More specifically, increases in Mg/Ca occur synchronously with previously
501   noted $\delta^{18}O$ excursions at 5668 ± 43, 5404 ± 44, 5363 ± 50, and 5308 ± 63 yr BP. This result,
502   along with significant correlations between Mg/Ca, $\delta^{13}C$ and $\delta^{18}O$, supports the interpretation of
503    $\delta^{18}O$ as a proxy for local moisture availability.

504

505   However, we also note periods where $\delta^{18}O$ and the other three proxies diverge. One example
506   occurs at 5571 ± 65 yr BP, where $\delta^{13}C$, Sr/Ca, and Mg/Ca all increase rapidly a few years after
507   an increase in $\delta^{18}O$ (Figure 4, noted with tan bar); the trace element and $\delta^{13}C$ values lag behind
508   the $\delta^{18}O$. These anomalies could be related to threshold behavior in the epikarst, meaning that
509   increases in prior calcite precipitation, water-rock interactions, and degassing, and therefore
510   increases in Sr/Ca, Mg/Ca, and $\delta^{13}C$, happen more slowly than the $\delta^{18}O_{precip}$ signal is transmitted
511   to the stalagmite.

512

513   As indicated above, Sr/Ca behaves differently from Mg/Ca during several events in the RS1
514   record; these events are one source of low correlation between Sr/Ca and other proxies. For
515   example, during the dry anomaly centered at 5404 ± 44 yr BP (Section 3.2.2), there is a
516   synchronous increase in $\delta^{18}O$, $\delta^{13}C$, and Mg/Ca ratios, but not Sr/Ca (Figure 4). Increased proxy
517   values suggest a 20-year-long period with drier hydroclimate, which we report with high

518 confidence because of the significant correlations and similar event duration between 3 of the 4
519 proxies (Figure 4). During the 50-year-long window encompassing that event, there are
520 significant positive correlations between $\delta^{18}O$, $\delta^{13}C$, and Mg/Ca, but not with Sr/Ca; in fact, there
521 is a significant negative correlation between $\delta^{13}C$ and Sr/Ca (Figure 5b).
522
523 Furthermore, when Sr/Ca was measured in modern farmed calcite and drip water from RS,
524 results indicated that Sr/Ca was not correlated with precipitation amount on monthly timescales
525 (Lases-Hernandez, 2020). The lack of correlation was ascribed to a lack of major differences in
526 precipitation amount during the calcite growth. In combination with the calcite results reported
527 here, it appears that there are additional factors controlling Sr/Ca in RS. These primary drivers
528 could include sea spray and calcite growth rate changes; previous research in RS demonstrated
529 that the drip water was enriched in chloride in comparison to rainfall (Lases-Hernandez, 2020).
530
531 *3.3.1 Relationship with drip water trace element compositions*
532 Regression of the calcite Mg/Ca and Sr/Ca data in log space yielded a nearly flat slope (m =
533 0.17; Figure 6). This result suggests that PCP was not the dominant control on Mg/Ca and Sr/Ca
534 during the mid-Holocene (Sinclair et al., 2012). Instead, the regression yields a slope similar to
535 that reported to relate to water-rock interactions (m = 0.18), including calcite recrystallization
536 (Sinclair et al., 2012). Therefore, calcite recrystallization could be the main driver of variability
537 in Mg/Ca and Sr/Ca ratios (Sinclair et al., 2012). During the last part of the record (5700 years
538 BP onward), the data have a different slope (m = 1.11, n < 40 samples), which could indicate
539 prior calcite precipitation leading into the hiatus at the top of the sample.
540
541 Lases-Hernandez (2020) reports that there is active PCP in the modern cave. Therefore, the lack
542 of evidence for PCP in trace element ratios from RS1, when considered alongside stable isotope
543 data that suggest a wetter hydroclimate during the mid-Holocene, supports increased
544 precipitation in comparison to the late Holocene and today. We cannot definitively confirm
545 whether there was PCP in the pre-industrial late Holocene, however, without trace element ratios
546 from a late Holocene stalagmite. Therefore, Mg/Ca may provide an independent tool to assess
547 whether the stable isotope data primarily reflect hydrological changes in RS, but Mg/Ca needs to
548 be more broadly applied to be most useful.

*Figure 6. Cross plot of Sr/Ca and Mg/Ca ratios for RS1. The RS1 data have a nearly flat slope (m = 0.17). Higher slopes (m = 0.7 – 1) associated with prior calcite precipitation (Sinclair et al., 2012) are shown for reference, but do not match the RS1 data.*

3.4. Spectral Analysis

We used wavelet analysis to quantitatively examine periodicity (supporting information). The limited window captured by the stalagmite means that it is difficult to find long-term periodicity that is statistically significant, but the proxies recorded signals with 32-128 year periods with limited statistical significance (supporting information). Due to the lack of robust periods, we will focus on other types of comparisons.

3.5 Comparison to other records

There are several existing paleoclimate records from the YP region (see Section 1 for a longer summary), including both sediment and speleothem records. Here we compare RS1 to three such records: Lago Puerto Arturo (LPO) from Wahl et al. (2014), which used stable isotope ratios as proxies for hydroclimate; Chen Ha from Pollock et al. (2016), a stalagmite with a similar resolution covering a similar time period (Figure 7); and GU-RM1, a speleothem from Grutas del Rey Marcos, Guatemala in Winter et al. (2020), which provides longer context for RS1. The LPO core and GU-RM1 speleothem each have a much lower resolution than RS1 or Chen Ha, with only 9 data points from LPO and 8 from GU-RM1 during the RS1 growth period (Figures 7 and 8).

571　Qualitatively, however, the RS1 and LPO oxygen isotope records have a very similar pattern,
572　with an increase toward wetter conditions around 5675-5650 yr BP, followed by a shift back to
573　drier conditions after 5600 yr BP. RS1 appears to be a higher resolution version of the Wahl et
574　al. (2014) record from the beginning to 5550 yr BP (Figure 7).
575
576　Pollock et al. (2016) does not show the same change toward wetter conditions around 5775 and
577　has a different or lagged pattern than the other two records from 5700 to 5500 yr BP (Figure 7);
578　for example, the maximum δ^{18}O value in RS1 occurs at 5571 yr BP, and the Chen Ha sample has
579　a similarly shaped local maximum at 5556. A lead or lag of ~25 years would be within age
580　model uncertainty for both Pollock et al. (2016) and RS1.

581　*Figure 7. Oxygen isotope ratio data for RS1 (this study, a), a sediment core from Lago Puerto*
582　*Arturo (Wahl et al., 2014; b), and Chen Ha, a speleothem from Belize (Pollock et al., 2016; c).*
583　*Data are plotted without resampling or smoothing.*
584

585

586
587 *Figure 8. Longer records from Guatemala covering the mid- and late Holocene. a, a sediment*
588 *core from Lago Puerto Arturo (Wahl et al., 2014) and b, a speleothem from Grutas de Rey*
589 *Marcos (Winter et al., 2020).*
590
591 In context with longer YP records, such as those of Wahl et al. (2014) and Winter et al. (2020)
592 from Guatemala, RS1 grew at the end of what previous studies have called the wetter mid-
593 Holocene or stable regime (Figure 8). We compared RS1 to these two datasets because they each
594 encompass the full length of RS1, plus several thousand years before and after its growth. RS1
595 stopped growing at 5234 ± 134 yr BP, just as a centennial-scale drying period began in the
596 Winter et al. (2020) speleothem (Figure 8).
597
598 Itzamna, a stalagmite from RS that grew during a more recent time period than RS1 (~3000-1500
599 years BP), has been used to study the Maya Terminal Classic Period. Because these two
600 stalagmites came from the same cave and have similar dating errors, comparing them allows for
601 a more robust analysis of precipitation variability and amount over time. The late Holocene
602 Itzamna $\delta^{18}O$ record has a lower resolution, with an average of 8 years per sample, so we applied
603 an 8-year low-pass Butterworth filter to the higher resolution RS1 $\delta^{18}O$ record. This filtering
604 method served to remove any variance that would not have been captured in the Itzamna record.
605

606

607 *Figure 9. a. Time series records of $\delta^{18}O_{calcite}$ in Itzamna (Medina-Elizalde et al., 2016a) and RS1.*
608 *b. Standard deviation of 500-year-long snapshots of $\delta^{18}O_{calcite}$ from Itzamna (Medina-Elizalde et*
609 *al., 2016a) and RS1 (after applying an 8-year low-pass Butterworth filter).. Variability and*
610 *median $\delta^{18}O$ are both significantly lower in RS1 than in Itzamna (F-test for variance, p <<*
611 *0.001; Mann-Whitney U-test for median, p << 0.001).*

612

613 The median $\delta^{18}O_{calcite}$ for Itzamna was -4.9‰, significantly less negative than RS1's median
614 $\delta^{18}O_{calcite}$ = -5.5‰ (Figure 8; Mann-Whitney U-test, p << 0.001). The variance in the two
615 stalagmites is also statistically different (F-test, p << 0.001), with RS1 showing less variability
616 than Itzamna (Figure 9). The variability in Itzamna increased over time, but was always greater
617 than that of RS1 (Figure 9).

618

619 **4 Discussion**
620 *4.1 Mid-Holocene hydrological variability in the RS1 record*
621 There are notable dry periods (more positive ratios, greater than 2SD above mean $\delta^{18}O_{calcite}$)
622 reaching local $\delta^{18}O$ maxima at 5668 ± 43 and 5571 ± 65 yr BP that lasted for 20-50+ years. We
623 note that some Mesoamerican droughts in both the Common Era and the past century had similar
624 multi-decadal lengths (*e.g.* Medina-Elizalde et al., 2016a). This similarity shows that multi-
625 decadal precipitation cycles are an integral feature of YP hydroclimate, occurring even during a

626   period of inferred higher mean precipitation and reduced precipitation variance. Both of the
627   multi-decadal dry periods have a sawtooth pattern in the $\delta^{18}O_{calcite}$, with slow drying and a rapid
628   change back to wetter conditions. Although the $\delta^{18}O_{calcite}$ was only outside the 2σ envelope
629   briefly (a few years at the inferred maximum of the dry period), the slow drying lasted for
630   decades.
631
632   The RS1 record also revealed three shorter dry intervals (duration $\leq$ 20 years) at 5404 $\pm$ 44, 5363
633    $\pm$ 50, and 5308 $\pm$ 63 yr BP, noted as anomalies in both stable isotope and Mg/Ca data, which
634   were previously undetected in lower resolution records (*e.g.* Wahl et al., 2014). In addition,
635   although wet intervals are less well-studied than droughts in the YP, we also found a ~20 year-
636   long event with a local $\delta^{18}O$ minimum at 5493 $\pm$ 40. These short events were only detected
637   because of the ~annual sampling resolution of RS1.
638
639   Taken together, the qualitative agreement and the statistical correlations between trace elements
640   and stable isotopes show that it is feasible to use $\delta^{18}O$, $\delta^{13}C$, and Mg/Ca as paleoclimate proxies
641   in this region on multi-year timescales. Furthermore, we suggest that it is prudent to collect data
642   on multiple types of proxies because they record hydrological variability in different ways,
643   potentially enriching the interpretation of the record.
644
645   *4.2 Comparison to other records*
646   Analysis of RS1 compared to Itzamna showed decreased variability and increased mean $\delta^{18}O$ in
647   the mid-Holocene compared to the late Holocene. Because both samples come from the same
648   cave, we assume that the differences in the variability of both $\delta^{18}O$ records are only due to
649   changes in hydroclimate over time and not due to temperature variance or inter-cave differences,
650   as might be the case when using stalagmites from two different caves for temporal comparisons.
651   Lower average $\delta^{18}O_{calcite}$ during the mid-Holocene (RS1 growth period) suggests that there was
652   more precipitation than during the late Holocene. Trace element ratios with a lack of evidence
653   for PCP (despite the presence of PCP in present-day RS) also support a wetter mid-Holocene, as
654   the aquifer may have been too wet for PCP to occur in the epikarst.
655
656   These observations are consistent with results from previous sediment and stalagmite studies in
657   Belize that found wetter, less variable mid-Holocene hydroclimate (*e.g.* Metcalfe et al., 2009;
658   Pollock et al., 2016) in comparison to the later Holocene. Lacustrine records from the YP also
659   showed higher mid-Holocene lake levels (*e.g.* Hodell et al., 1995; Whitmore et al., 1996), and a
660   series of calcite rafts from other caves in the YP show progressive drying from 7,000 years BP to
661   the present (Kovacs et al., 2017). While it is possible that the difference in $\delta^{18}O$ between RS1
662   and Itzamna is not *solely* due to decreased precipitation amount, the similarity between our
663   findings and published data suggests that the northeastern YP, like Belize and Guatemala, was
664   wetter during the mid-Holocene than the late Holocene.
665
666   The apparent ~25 year lead/lag between Pollock et al. (2016) and RS1 is within age model
667   uncertainty for both stalagmites, so it is possible that the two records are actually changing
668   synchronously at a decadal scale. If there is indeed a lag between the major shifts in oxygen
669   isotope ratios, that would indicate the presence of a precipitation control that first impacted the
670   northern YP and did not affect the southern YP and Belize until later. Regional agreement among
671   these paleoclimate records, across proxies and archives, within age model uncertainty suggests

672   that the driver of increased precipitation amount and decreased precipitation variability is not
673   isolated to this cave site or restricted to this short interval of the mid-Holocene. Instead, the
674   driver(s) is at least regional in scale, and persisted for a large portion of the mid-Holocene.
675
676   Furthermore, comparing RS1 to the sediment record from LPO (Wahl et al., 2014) showed that
677   the δ^{18}O shifts seen in the southern YP between ~5750-5550 yr BP are reproducible at higher
678   temporal resolution and are qualitatively similar to those found a different archive from the
679   northern YP. The coherence between the records further supports the use of δ^{18}O to reconstruct
680   past hydroclimate in Mesoamerica.
681
682   Based upon the longer records shown in Figure 8, it appears that RS1 captured a representative
683   part of the mid-Holocene, not an extremely wet or variable period, so we suggest that the ~500
684   year-long RS1 record applies to the whole mid-Holocene. We now explore potential drivers of
685   increased precipitation amount and reduced variability in the mid-Holocene.
686
687   Increased precipitation amount is likely due (in part) to increased insolation seasonality during
688   the mid-Holocene, which preferentially warmed North Atlantic summer SSTs, promoting
689   increased YP precipitation via enhanced moisture transport by the CLLJ and a more northerly
690   mean position of the Atlantic ITCZ. This link between North Atlantic SSTs and YP precipitation
691   has been observed in the instrumental record and model simulations (Bhattacharya et al., 2017),
692   and has been invoked to explain other observed proxy records (Ridley et al., 2015; Pollock et al.,
693   2016). More recent work, however, emphasizes the importance of the pressure gradient between
694   the western tropical Atlantic and the eastern tropical Pacific in driving Mesoamerican
695   precipitation variability over the last millennium (Bhattacharya and Coats, 2020), suggesting that
696   wet mid-Holocene conditions in the YP may also have required relatively high SLP over the
697   eastern tropical Pacific.
698
699   Increased tropical cyclone activity could have been partially responsible for higher YP
700   precipitation in the mid-Holocene. Pausata et al. (2017) modeled tropical cyclone activity at 6
701   kyr BP and demonstrated that increased seasonality, a vegetated Sahara, and a reduction in
702   Saharan dust emissions could lead to an increase in tropical cyclones during the mid-Holocene,
703   especially in the Caribbean. Under modern conditions, RS is impacted by a greater number of
704   historical tropical cyclones, but has less total summer precipitation than the Guatemala and
705   Belize regions of the YP (Section 1). Therefore, an increase in tropical cyclones would have a
706   larger impact on the northern YP than in the south, potentially explaining why the δ^{18}O change
707   appears larger in RS1 than in the records from the southern YP (Figure 8). We cannot resolve
708   individual high-precipitation events in our record due to the nature of water infiltration into the
709   karst at RS, so other types of archives would be better suited to specifically identify the impact of
710   individual tropical cyclones in the YP during the mid-Holocene.
711
712   Lower precipitation variability during the mid-Holocene could be related to reduced ENSO
713   variability. Several studies have shown that the mid-Holocene was a period of reduced ENSO
714   variance compared to the late Holocene (Carré et al., 2014; Chen et al., 2016; Emile-Geay et al.,
715   2016; Koutavas et al., 2006; Koutavas and Joanides, 2012). Summer CLLJ variability is thought
716   to be linked to tropical Pacific variability (Muñoz et al., 2008), so decreased Pacific SST
717   variability could lead to a more stable CLLJ, yielding the diminished precipitation variation we

718 observe in RS1. Furthermore, previous modeling, monitoring, and proxy data have suggested
719 that ENSO mean state influences tropical Atlantic cyclone formation (Elsner et al., 1999;
720 Frappier et al., 2014; Lases-Hernandez et al., 2019; Medina-Elizalde et al., 2016b; Wu & Lau,
721 1992). Therefore, decreased ENSO variability during the mid-Holocene could reduce changes in
722 the frequency of tropical cyclones, further decreasing the amplitude of precipitation variability in
723 the YP.
724
725 Our study contributes to a wide range of work linking changes in Atlantic SSTs, including
726 Atlantic Multidecadal Variability (AMV), to Caribbean and Gulf of Mexico hydroclimate
727 (Alexander et al., 2014; Battacharya et al., 2017; Karmalkar et al., 2011; Knight et al., 2006;
728 Winter et al., 2020). The high-resolution data presented here will allow for comparisons with
729 SST reconstructions to better understand how future SST shifts will impact Central American
730 hydroclimate. Instrumental, paleoclimate, and modeling data also support a link between AMV
731 and hydroclimate over multiple other regions, including the North Atlantic (Knight et al., 2006),
732 northeastern Brazil (Sutton et al., 2005), African Sahel (Folland et al., 1986; Rowell et al., 1992),
733 western Europe (Folland et al., 1986; Knight et al., 2006; Sutton et al., 2005), and North America
734 (Fensterer et al., 2012; Folland et al., 2001; Medina-Elizalde et al., 2017). Future work should
735 examine whether paleoclimate records with decadal-scale resolution from these other regions
736 also show reduced variance in the mid-Holocene relative to the late Holocene.
737
738 Regardless of the climate dynamics at play, the anomalous precipitation events (both those less
739 than 20 years long and others that were 20-50 years long) observed in RS1 indicate significant
740 multidecadal wet-dry cycles, much like there are in the present and late Holocene YP, despite the
741 wetter, warmer climate state of the mid-Holocene. Thus, we expect similar, multidecadal
742 droughts both under future climate warming and in other paleoclimate records from this region,
743 including others that overlap with shifts in ancient Maya society.
744
745 **5 Conclusions**
746 In this study, we have presented a precisely dated, high-resolution, multi-proxy YP paleoclimate
747 record spanning a 463-year-long interval (5727 ± 79 to 5264 ± 134 yr BP) of the mid-Holocene.
748 Results from this study suggest that multi-decadal precipitation variations (both wet and dry)
749 were a persistent feature in regional hydroclimate during the mid-Holocene, just as they were in
750 the past 2 millennia, but with reduced amplitude. The record is consistent with previous
751 observations of southern YP hydroclimate, which found increased precipitation in the mid-
752 Holocene. High-resolution proxy sampling (1.3 years per sample) in RS1 also allowed us to
753 detect anomalous precipitation events with durations of less than 20 years.
754
755 Because the mid-Holocene had a different climate mean state (more summer solar input and
756 higher mean precipitation) than the late Holocene, we conclude that background climate can
757 impact precipitation variability in the YP. We suggest that mid-Holocene reductions in ENSO
758 and/or AMV variability, driven by altered seasonality, led to more stable precipitation patterns
759 throughout the YP. As background climate changes under anthropogenic warming conditions, it
760 will be important to examine changes in precipitation mean and variance indicated by climate
761 models. Model simulations of future hydroclimate can be tested by comparing predicted variance
762 at 6 kyr BP to that recorded in other proxy records and 6 kyr models. Given that the YP is
763 already vulnerable to tropical cyclones and may also face decreased wet season precipitation in

the future, it is critical for projections to be as accurate as possible. We suggest that the mid-Holocene offers an important test for model performance that can be used to assess the substantial disagreements between future projections in the region (Bhattacharya & Coats, 2020), providing improved confidence in climate adaptation strategies for its approximately 4 million residents.

Although stalagmites provide only a short snapshot of hydroclimate during their growth period, this study demonstrates the utility of single-cave, multi-stalagmite analyses, especially when considering changes in variability over time. This work presents the first record of stalagmite Mg/Ca and Sr/Ca ratios in the Yucatán Peninsula. Our results support the inclusion of trace element ratios in stalagmites that cover changes in ancient Maya civilization to provide additional climate information. These results are a step forward in YP paleo proxy interpretations and provide a better understanding of controls on precipitation amount and variability.
